-- The MAILING DATE of this communication appears on the cover sheet with the correspondence address --
Period for Reply

A SHORTENED STATUTORY PERIOD FOR REPLY IS SET TO EXPIRE 3 MONTH(S) OR THIRTY (30) DAYS, WHICHEVER IS LONGER, FROM THE MAILING DATE OF THIS COMMUNICATION.

- Extensions of time may be available under the provisions of 37 CFR 1.136(a). In no event, however, may a reply be timely filed after SIX (6) MONTHS from the mailing date of this communication.
- If NO period for reply is specified above, the maximum statutory period will apply and will expire SIX (6) MONTHS from the mailing date of this communication.
- Failure to reply within the set or extended period for reply will, by statute, cause the application to become ABANDONED (35 U.S.C. § 133). Any reply received by the Office later than three months after the mailing date of this communication, even if timely filed, may reduce any earned patent term adjustment. See 37 CFR 1.704(b).

Status

- 1) ☒ Responsive to communication(s) filed on 03 March 2006.
- 2a) ☐ This action is **FINAL**. 2b) ☒ This action is non-final.
- 3) ☐ Since this application is in condition for allowance except for formal matters, prosecution as to the merits is closed in accordance with the practice under *Ex parte Quayle*, 1935 C.D. 11, 453 O.G. 213.

Disposition of Claims

- 4) ☒ Claim(s) 1-10, 13-17, 20-28, 30 and 32-41 is/are pending in the application.
- 4a) Of the above claim(s) _____ is/are withdrawn from consideration.
- 5) ☒ Claim(s) 8-10, 13, 20 and 39-41 is/are allowed.
- 6) ☒ Claim(s) 1-7, 14, 21-27, 30 and 32-38 is/are rejected.
- 7) ☒ Claim(s) 16, 17 and 28 is/are objected to.
- 8) ☐ Claim(s) _____ are subject to restriction and/or election requirement.

Application Papers

- 9) ☐ The specification is objected to by the Examiner.
- 10) ☐ The drawing(s) filed on _____ is/are: a) ☐ accepted or b) ☐ objected to by the Examiner.
Applicant may not request that any objection to the drawing(s) be held in abeyance. See 37 CFR 1.85(a).
Replacement drawing sheet(s) including the correction is required if the drawing(s) is objected to. See 37 CFR 1.121(d).
- 11) ☐ The oath or declaration is objected to by the Examiner. Note the attached Office Action or form PTO-152.

Priority under 35 U.S.C. § 119

- 12) ☐ Acknowledgment is made of a claim for foreign priority under 35 U.S.C. § 119(a)-(d) or (f).
- a) ☐ All b) ☐ Some * c) ☐ None of:
- ☐ Certified copies of the priority documents have been received.
 - ☐ Certified copies of the priority documents have been received in Application No. _____.
 - ☐ Copies of the certified copies of the priority documents have been received in this National Stage application from the International Bureau (PCT Rule 17.2(a)).
- * See the attached detailed Office action for a list of the certified copies not received.

DETAILED ACTION

Response to Arguments

Applicant's arguments, see Remarks pages 1-4 and claim amendments, filed 3 March 2006, with respect to the rejection(s) of claim(s) 1-10, 13, 21-27, 29, and 32-38 under various statutes have been fully considered and are partially persuasive as explained below.

Applicant has clarified what means correspond to what function (see Remarks page 1, bottom of page) with regards to claims 8-10 and 13.

The rejection of claims 8-10 and 13 under 35 USC 112, second paragraph, as failing to comply with the requirements of 35 USC 112, sixth paragraph, stands withdrawn since applicant has met the requirements as recited above.

The objection to the drawings stands withdrawn as per the above; it was made in conjunction with rejection of claims 8-10 and 13 under 35 USC 112, second paragraph.

The coupled objection to the specification also stands withdrawn for the same reasons as above.

Applicant's arguments with respect to claims 1-7, 21-27, and 32-38 are **not** found to be persuasive in all regards. However, **in light of applicant's amendments to the claims** and in order to expedite prosecution, examiner has added a teaching reference that covers applicant's addition of intended of specific language to the claims.

Art Unit: 2628

The rejections of claims 1-7, 21-27, and 32-38 under 35 USC 103(a) in view of Wilson, Willson, and various other references stands withdrawn.

New grounds of rejection follow below.

Additionally, it shows that in the art of image processing, the terms 'convolution' and 'filtering' are synonymous, and that applicant's assertion that FIR digital filters are not analogous field for one skilled in the art of computer graphics is mistaken. One skilled in computer graphics **that was performing image convolution operations** would inherently be familiar with the various kinds of filters used in the art, where filters are used for filtering images and any other digital signal representing some phenomenon – see for example edge detection and the like. Examiner upon request by applicant to this effect will provide substantial evidence; applicant is kindly requested to immediately communicate intent to request such material to examiner, so that it can rapidly be made of record.

Allowable Subject Matter

Claims 8-10, 13, and 39-41 are allowed for the reasons discussed in the previous Office Actions, since applicant has corrected the deficiencies that they contained and they were previously indicated allowable.

Claims 16-17 and 29 are objected to as being dependent upon a rejected base claim, but would be allowable if rewritten in independent form including all of the limitations of the base claim and any intervening claims, as discussed in the last Office Action.

Art Unit: 2628

It is noted that the 'means' recited in claim are assumed to be the SM ASIC in Figure 8, as discussed on pages 9-10 of the instant specification.

Allowable Subject Matter

The indicated allowability of claims 14-17 is withdrawn in view of the newly discovered reference(s) to Bui. Rejections based on the newly cited reference(s) follow.

Definitions

The term 'rendered' is not defined by applicant's specification. The standard definition for 'rendered' in the context of computer graphics is that an image that is digitized and exists within some type of memory or storage, volatile or nonvolatile, is processed and sent to a display device – such as a LCD, CRT, and the like.

This definition is consistent with the intrinsic record. Examiner is giving claims their broadest reasonable interpretation as per MPEP 2105.

Further, the term 'convolution' in the context of digital signal and image processing has certain meanings. An image convolution is inherently a filtering operation. Further, in mathematics, the definition of a kernel (one definition) of a function (e.g. convolution) is: the equivalent relation on the function's domain that roughly expresses the idea of "equivalent as far as the function f can tell". However, the point is that image convolution represents a function, and that function has a *kernel* in the mathematical sense that conveys the operation of the function. Therefore, any convolution operation will inherently have a kernel. See as an example Bui 1:5-2:45.

Art Unit: 2628

Bui, which is substituted for Willson, provides a full explanation of how convolution is equivalent to filtering and Bui is **clearly** analogous art, since it convolves images.

Claim Rejections - 35 USC § 112

The following is a quotation of the second paragraph of 35 U.S.C. 112:

The specification shall conclude with one or more claims particularly pointing out and distinctly claiming the subject matter which the applicant regards as his invention.

Claim 14 is rejected under 35 U.S.C. 112, second paragraph, as being indefinite for failing to particularly point out and distinctly claim the subject matter which applicant regards as the invention.

Specifically, the claim recites the number 'N' without specifying the range of such a number. Therefore, the claim is indefinite. Also, if N were negative, that would make no sense.

Specifically, if there were only one sample manager, it would therefore calculate partial sums – but if N is 0, then no partial sums would ever be calculated for anything, and the system would not work as designed.

Therefore, if k were zero, where N could be zero, the system could never work in the manner that the claim specifies, because if it were, there would be no processing elements or sample elements, but would only be a singular partial sums bus, connected to nothing.

Claim Rejections - 35 USC § 103

The following is a quotation of 35 U.S.C. 103(a) which forms the basis for all obviousness rejections set forth in this Office action:

(a) A patent may not be obtained though the invention is not identically disclosed or described as set forth in section 102 of this title, if the differences between the subject matter sought to be patented and the prior art are such that the subject matter as a whole would have been obvious at the time the invention was made to a person having ordinary skill in the art to which said subject matter pertains. Patentability shall not be negated by the manner in which the invention was made.

The factual inquiries set forth in *Graham v. John Deere Co.*, 383 U.S. 1, 148 USPQ 459 (1966), that are applied for establishing a background for determining obviousness under 35 U.S.C. 103(a) are summarized as follows:

1. Determining the scope and contents of the prior art.
2. Ascertaining the differences between the prior art and the claims at issue.
3. Resolving the level of ordinary skill in the pertinent art.
4. Considering objective evidence present in the application indicating obviousness or nonobviousness.

Claims 1-2 are rejected under 35 U.S.C. 103(a) as being unpatentable over Wilson (US 5,129,092) in view of Bui et al (US 4,998,288 A).

As to claim 1,

A computer graphics system for generating pixels from a distributed convolution of rendered samples comprising: (Wilson processes images Wilson is designed

Art Unit: 2628

to process images in 8x8 bit submatrices, as in Abstract, and 2:45-3:4, where an image inherently consists of pixels. Wilson performs convolution (18:20-60) on sections of an image broken down into smaller data pieces (1:5-20), utilizing a plurality of processors 10a-10n, which therefore constitutes 'distributed processing')(Bui teaches image convolution – 1:10-2:30, where the process of convolution, dividing an image into smaller kernels and performing filtering is explained; see 3:10-35 where a general purpose digital convolver of the present invention is explained)

-A plurality of sample managers connected in series; and (Wilson clearly teaches in Abstract and in Figure 1 a plurality of processor groups each comprising of individual processing elements 10a-10h, wherein each group of elements is connected to the element adjacent to it using data lines 11i-11n and register shift lines 21i-21n, as set forth in 5:55-6:34, these elements are clearly connected in series (as in 2:45-60, where it states that these elements are connected in a **linear chain**, where in Figure 1 it is clear that is input from data input device 20 over lines 21a and then passed in a one-way manner down the line on lines 21i→21n))(Bui Figure 2 teaches a plurality of sample managers, e.g. filter elements in rows, that constitute parallel sums, which are similar to those found in Wilson as above, where each element generates a result and passes it down the chain – see the multipliers and adders, where each multiplier has a preassigned coefficient value – see 3:50-65 – e.g. one of the coefficients of the 3x3 convolution kernel – e.g. the filter)

Art Unit: 2628

-A set of partial sums buses, wherein each partial sums bus connects one of the sample managers of the series to the next sample manager in the series; (Wilson – the term **bus** is well known in the art to merely mean one or more data transfer lines, wherein the data lines 11i-11n and 21i-21n clearly move data in byte-size chunks, which therefore mean that they are “buses” in the sense meant by applicant. Clearly, these buses can transfer partial sums, as in 18:20-60, where it is noted that partial sums can be moved along the chain of processors)(Bui – clearly the connections between each element constitute a sample bus – the original data enters the pipeline and is weighted, then is subjected to a delay and placed on the partial sum bus and passed down the addition nodes on the accumulator lines)

-Wherein each sample manager is operable to calculate partial sums for a corresponding portion of the rendered samples located within a convolution kernel corresponding to a pixel location, wherein the partial sums comprise 1) a sum of weights determined for locations of the rendered samples in the portion of rendered samples and 2) a sum of weighted sample values for the portion of rendered samples, (Wilson is designed to process images in 8x8 bit submatrices, as in Abstract, and 2:45-3:4. Further, in 1:10-35 Wilson teaches that inherently, data arrays such as images must be broken into smaller data array sizes with dimensions equivalent to the size of the processor array. Therefore, the recited ‘convolution kernel’ in applicant’s specification consists a certain N x N region, as noted in Remarks page 1, of which the 8x8 sub-matrix or sub-array of Wilson would clearly qualify. Clearly, the resultant element is passed down the

Art Unit: 2628

processor line to be operated upon, which provides a sum of weighted values for that portion of samples. Further, in 18:20-60 it is clearly explained that the system is intended to handle convolutions and/or sums as part of processing images, where these can clearly be partial sums. Wilson very clearly teaches many common tasks in image filtering, such as transposes (16:40-50), accumulation (19:20-60), and the like (16:53-18:20, 18:60-19:50)(Bui - Separate regions of the images are convolved – 4:34-40 – every pixel in the image is subjected to the convolution kernel and serves as the center point in it before processing is completed. Bui 2:33-50 provides that video pixel elements that fall within the convolution kernel are firstly weighted using multipliers having preassigned coefficients, which are then added together. See for example Figure 2 – each pixel is firstly sent through a multiplier M02 where it is weighted, then along a sample bus 2B through a delay element to an adder A01. This continues down the chain, where each weighted element is added to the bus line and passed down. In other words, the coefficients assigned to the multipliers comprise a sum of weights for the various elements, and at the end of each branch, a partial sum is output. Then, that partial sum from that row is passed along another partial sum bus to another delay element H, where the master partial sum bus then adds the row output partial sums together and a final value is output as convolved video output 210.)

-Wherein each of the second through the last sample manager in the series is operable to add the partial sums calculated for its corresponding portion of the rendered samples to any previously accumulated partial sums received from the

Art Unit: 2628

prior sample manager in the series, and if not the last sample manager in the series, output new accumulated partial sums to the next sample manager in the series. (Wilson clearly teaches that for the accumulator model, each group of processing elements passes the partial sums along towards the right. Clearly, the system will take the partial sums calculated for its portion of the same sample and output the results to the next group of processing elements in the series)(Bui Figures 2-4 clearly show that the partial sums produced by any element that is not the first in a chain is passed down the partial sums bus, with the output of that particular element added to the result already in the partial sums bus, and that result is passed down the chain. The last element in the chain outputs the convolved video output).

Wilson per se teaches most of the limitations of the above claim, but does not expressly teach certain details of how a chain of linear accumulation elements for an image-processing filter would operate, and expressly stating how image convolution works, along with explaining the partial sums weighting process more completely.

The Bui reference is added to explicitly cover certain details of how a chain of linearly connected accumulation elements for an image-processing filter would operate, with respect to how various elements of a sequence of processing elements would communicate with regards to partial sums transmission, and that the results are passed down the partial sums busses and added together. It would have been obvious to one of ordinary skill in the art at the time the invention was made to combine the systems of Wilson and Bui

Art Unit: 2628

because the system of Bui induces less delays and can operate in a faster manner for purposes of convolution of specific elements – see for example (5:1-20) that avoids the known larger delays in the prior art, such as 4:46-57. Where clearly the system of Wilson is 2:45-60 is specified to perform image processing and convolution, as well as accumulation operations, the Wilson reference is silent on how that actually implements image filtering. The Bui reference clearly performs image filtering using weighted partial sums buses as defined above, where in 1:63-2:2 it is specified how accumulation processes are used in image convolution.

As to claim 2, clearly Wilson is computing image data as noted above, so the last sample manager would clearly calculate pixel values, where the output data is clearly computed by the final element and sent out from the final unit using data line 21p to output device 22, which clearly shows that such data is image data, and the like.

Bui clearly performs image convolution at the last output manager, adds all the partial sums together, and generates the convolved video output (210, 310, 410 – Figures 2, 3, and 4).

As to claim 14,

A system for distributed filtering of samples comprising: (Wilson processes images Wilson is designed to process images in 8x8 bit submatrices, as in Abstract, and 2:45-3:4, where an image inherently consists of pixels. Wilson performs convolution (18:20-60) on sections of an image broken down into smaller data pieces (1:5-20), utilizing a plurality of processors 10a-10n, which

Art Unit: 2628

therefore constitutes 'distributed processing')(Bui teaches image convolution – 1:10-2:30, where the process of convolution, dividing an image into smaller kernels and performing filtering is explained; see 3:10-35 where a general purpose digital convolver of the present invention is explained. **Clearly, image pixels constitute samples.**)

-A series of N sample managers (k), wherein k is an integer with range 0 to N-1; (Wilson clearly teaches in Abstract and in Figure 1 a plurality of processor groups each comprising of individual processing elements 10a-10h, wherein each group of elements is connected to the element adjacent to it using data lines 11i-11n and register shift lines 21i-21n, as set forth in 5:55-6:34, these elements are clearly connected in series (as in 2:45-60, where it states that these elements are connected in a **linear chain**, where in Figure 1 it is clear that is input from data input device 20 over lines 21a and then passed in a one-way manner down the line on lines 21i→21n))(Bui Figure 2 teaches a plurality of sample managers, e.g. filter elements in rows, that constitute parallel sums, which are similar to those found in Wilson as above, where each element generates a result and passes it down the chain – see the multipliers and adders, where each multiplier has a preassigned coefficient value – see 3:50-65 – e.g. one of the coefficients of the 3x3 convolution kernel – e.g. the filter)

-A partial sums bus connecting each sample manager (k) in the series of sample managers to the next sample manager (k+1); (Wilson – the term **bus** is well known in the art to merely mean one or more data transfer lines, wherein the data lines 11i-11n and 21i-21n clearly move data in byte-size chunks, which

Art Unit: 2628

therefore mean that they are "buses" in the sense meant by applicant. Clearly, these buses can transfer partial sums, as in 18:20-60, where it is noted that partial sums can be moved along the chain of processors)(Bui – clearly the connections between each element constitute a sample bus – the original data enters the pipeline and is weighted, then is subjected to a delay and placed on the partial sum bus and passed down the addition nodes on the accumulator lines)

-Receive accumulated partial sums from a prior sample manager (k-1), if k is greater than zero, wherein partial sums comprise partial sums for each parameter value, (Wilson is designed to process images in 8x8 bit submatrices, as in Abstract, and 2:45-3:4. Further, in 1:10-35 Wilson teaches that inherently, data arrays such as images must be broken into smaller data array sizes with dimensions equivalent to the size of the processor array. Therefore, the recited 'convolution kernel' in applicant's specification consists a certain N x N region, as noted in Remarks page 1, of which the 8x8 sub-matrix or sub-array of Wilson would clearly qualify. Clearly, the resultant element is passed down the processor line to be operated upon, which provides a sum of weighted values for that portion of samples. Further, in 18:20-60 it is clearly explained that the system is intended to handle convolutions and/or sums as part of processing images, where these can clearly be partial sums. Wilson very clearly teaches many common tasks in image filtering, such as transposes (16:40-50), accumulation (19:20-60), and the like (16:53-18:20, 18:60-19:50)(Bui - Separate regions of the images are convolved – 4:34-40 – every pixel in the image is

Art Unit: 2628

subjected to the convolution kernel and serves as the center point in it before processing is completed. Bui 2:33-50 provides that video pixel elements that fall within the convolution kernel are firstly weighted using multipliers having preassigned coefficients, which are then added together. See for example Figure 2 – each pixel is firstly sent through a multiplier M02 where it is weighted, then along a sample bus 2B through a delay element to an adder A01. This continues down the chain, where each weighted element is added to the bus line and passed down. In other words, the coefficients assigned to the multipliers comprise a sum of weights for the various elements, and at the end of each branch, a partial sum is output. Then, that partial sum from that row is passed along another partial sum bus to another delay element H, where the master partial sum bus then adds the row output partial sums together and a final value is output as convolved video output 210.)

-Calculate partial sums for a set of samples, wherein the set of samples are within a sub-set of screen space assigned to sample manager (k), and wherein the set of samples are located within a convolution kernel defined for a pixel, (Wilson, as discussed above, divides the screen into 8x8 submatrices for processing, which constitute a sub-set of screen space, which would be assigned to each block, as discussed above also, where the block would constitute a sample manager (k). Clearly, these are used for accumulation purposes)(Bui clearly teaches that a convolution kernel can be any width – the implementation provided of a 3x3 array is merely an example (3:10-45). As noted above, the convolution kernel is passed over each pixel in the image (or subset of an image)

Art Unit: 2628

(4:34-40). Therefore, the subset of screen space would be the 8×8 block of Wilson, and the convolution kernel provided by Bui could be applied, since the set of samples is not required to be the same size as the set of screen space, although for purposes of convenience, it could be)

-Add the partial sums to the sample manager (k+1), if k is less than N-1; and (Plainly meaning that if sample manager (k) is the last one in the series (e.g. $k = N - 1$), no partial sum addition would take place, since there would be no more sample managers to send the partial sums to – the addition process would be complete)(Wilson clearly teaches that for the accumulator model, each group of processing elements passes the partial sums along towards the right. Clearly, the system will take the partial sums calculated for its portion of the same sample and output the results to the next group of processing elements in the series)(Bui Figures 2-4 clearly show that the partial sums produced by any element that is not the first in a chain is passed down the partial sums bus, with the output of that particular element added to the result already in the partial sums bus, and that result is passed down the chain. The last element in the chain outputs the convolved video output).

-Wherein a designated sample manager is operable to calculate pixel values from the final accumulated partial sums (Wilson displays the results of the computations on an output display device, as shown as data output device 22 in Figure 1)(Bui clearly shows in Figures 2-4 that the output of the device is pixel values in video format, and that the output is 'convolved video' as element 210 in Figure 2, for example).

Art Unit: 2628

Wilson per se teaches most of the limitations of the above claim, but does not expressly teach certain details of how a chain of linear accumulation elements for an image-processing filter would operate, and expressly stating how image convolution works, along with explaining the partial sums weighting process more completely.

The Bui reference is added to explicitly cover certain details of how a chain of linearly connected accumulation elements for an image-processing filter would operate, with respect to how various elements of a sequence of processing elements would communicate with regards to partial sums transmission, and that the results are passed down the partial sums busses and added together. It would have been obvious to one of ordinary skill in the art at the time the invention was made to combine the systems of Wilson and Bui because the system of Bui induces less delays and can operate in a faster manner for purposes of convolution of specific elements – see for example (5:1-20) that avoids the known larger delays in the prior art, such as 4:46-57. Where clearly the system of Wilson is 2:45-60 is specified to perform image processing and convolution, as well as accumulation operations, the Wilson reference is silent on how that actually implements image filtering. The Bui reference clearly performs image filtering using weighted partial sums buses as defined above, where in 1:63-2:2 it is specified how accumulation processes are used in image convolution.

Art Unit: 2628

As to claim 15, clearly each group of elements in Wilson has the corresponding memory across to each group of processing elements in series – see Figure 1 as an example.

Claims 3, 21, 23, 25-27, 30, 32-33, and 36-37 are rejected under 35 U.S.C. 103(a) as being unpatentable over Wilson in view of Bui as applied to claims 1 and 2 above, and further in view of Inada et al (US 2004/0004620 A1)('Inada').

As to claim 3, the system of claim 2, wherein for each sample manager the corresponding portion of samples resides in a sub-set of screen space and the sub-sets are finely interleaved across screen space. --! -- Clearly the system of Inada establishes in [0154] that the system breaks the screen down into blocks of 4x4 pixels for interleaving, which constitutes a distribution across screen space, and further in Fig. 1 it is shown how the screen is divided into smaller areas, where each area is analyzed for the presence of a primitive in the pixels in that particularly, smaller area. Further, Wilson teaches the division of an image into blocks or sub-arrays for processing and convolution purposes. That being said, It would have been obvious to one having ordinary skill in the art at the time the invention was made to combine the systems of Wilson and Bui for the reasons set forth above (the motivation and combination of claim 2 are herein incorporated by reference) with the system of Inada, to allow interleaving as that technique speeds up drawing time (Inada [0155]).

Art Unit: 2628

As to claim 21, the rejection to claim 1 is incorporated by reference.

Firstly, the claimed filter unit as recited is clearly comparable to the sample managers recited in previous claims, as the functionality is the same, and the processing element would clearly be performing similar tasks. Each of the N memories recited is attached to a group of processing elements, which serves as a filtering element / sample manager / generic processor, as set forth in Wilson Fig. 1. Each unit of Willson could contain a convolution kernel, with the individual taps of the filter being the multipliers of Bui and the like. Clearly the system of Inada establishes in [0154] that the system breaks the screen down into blocks of 4x4 pixels for interleaving, which constitutes a distribution across screen space, and further in Fig. 1 it is shown how the screen is divided into smaller areas, where each area is analyzed for the presence of a primitive in the pixels in that particularly, smaller area, and in Fig. 7 the screen is shown to be divided into 2x2 bins or tiles containing samples for processing purposes. Further, Wilson teaches the division of an image into smaller arrays, as in Wilson is designed to process images in 8x8 bit submatrices, as in Abstract, and 2:45-3:4. Further, in 1:10-35 Wilson teaches that inherently, data arrays such as images must be broken into smaller data array sizes with dimensions equivalent to the size of the processor array.

Next, the recited N and k can clearly be 1. Obviously, the system of Wilson has one or more memory per processing group as connected in Figure 1 – see Wilson 5:55-6:45 and shown and the system of Inada has a graphics memory 145 with a memory interface circuit 144 as shown in Fig. 2, where

Art Unit: 2628

clearly this meets the recited limitations for the fact that N and k can be 1. Each unit of Bui is an individual tap of the filter or similar implementation. The recited numeric limitations – that of N and k, are obvious in that any chain of processors would have each processor numbered as set forth in the claim, with the respective limitations, in that, for example, the first processor in the chain would be numbered zero, and of course the first processor would *prima facie* not receive data from a previous processor as it was the first one in the processor chain.

As set forth in the preceding paragraph, each processor 10a-10h in the processing group in Wilson obviously reads from its own memory that contains the section of the image assigned to (as in Inada) for convolution purposes (or Wilson), performs partial sum calculations on it, and moves it into the next element in the linearly connected array (Wilson). The entire question of partial sums and their calculations is covered in the sections of the rejection of claim 1 that has been expressly incorporated via reference and will not be repeated for the purposes of brevity.

One additional note is that the system of Inada as shown in Fig. 4 clearly shows a plethora of operations units attached to each register (e.g. operation units 1411-1, 1412-1, etc. attached to registers such as 1411-2), which clearly establishes multiple processing / operations units attached to memories in the first place.

Obviously, the system of Inada outputs pixels as set forth in paragraphs [0022-0024]. Clearly, the results of all the graphics calculations and convolutions

Art Unit: 2628

would be passed out as pixel data as shown there, and it is logical that the end results of an image convolution calculation from a chain would indeed be output as pixels – indeed, an image is fundamentally composed of pixels, and it is a fundamental of the digital signal processing art that an image is output in pixels from being processed in this context.

Motivation and combination is taken from the rejection to claim 1, which is incorporated by reference, and from the additional logic as set forth above.

Inada brings in the benefits of explaining how the screen space is subdivided so that such an array can thusly more efficiently process all the information provided from the subdivision of the screen space. Motivation / rationale is also taken from the rejection to claim above.

As to claim 23, it is a substantial duplicate of claim 21 under the circumstances where M is 1. For other circumstances, obviously the system of Wilson can be dynamically reconfigured to support the desired arrangement of processing elements, depending on numbers of processors per group, as it could be composed of FPGAs that are fundamentally reprogrammable and/or could simply be programmed in a different manner, given that each processing group has so many processing elements. Therefore, division into groups is a trivially obvious variant. Also, Inada is **only** included for division of screen space, which examiner contends would be a notoriously and trivially obvious variant anyway.

As to claim 25, it is merely a method implementing the system of claim 21, and the rejection to claim 21 is valid upon it without further comment.

Art Unit: 2628

As to claim 26, see the rejection to claim 3 above, which addresses regions having defined boundaries, wherein the screen space is divided asset forth there. Inada [0020] discusses how each region is judged with respect to its center point, which clearly establishes that this is an obvious variation. Motivation and combination are taken from the parent claim and incorporated herein by reference in their entirety.

As to claim 27, this limitation is expressly covered in the rejection of claim 1, the relevant portion of which is incorporated by reference, and is also stated below. Wilson is designed to process images in 8x8 bit submatrices, as in Abstract, and 2:45-3:4. Further, in 1:10-35 Wilson teaches that inherently, data arrays such as images must be broken into smaller data array sizes with dimensions equivalent to the size of the processor array. Therefore, the recited 'convolution kernel' in applicant's specification consists a certain N x N region, as noted in Remarks page 1, of which the 8x8 sub-matrix or sub-array of Wilson would clearly qualify. Clearly, the resultant element is passed down the processor line to be operated upon, which provides a sum of weighted values for that portion of samples. Further, in 18:20-60 it is clearly explained that the system is intended to handle convolutions and/or sums as part of processing images, where these can clearly be partial sums. Wilson very clearly teaches many common tasks in image filtering, such as transposes (16:40-50), accumulation (19:20-60), and the like (16:53-18:20, 18:60-19:50). (Bui clearly teaches that the data is passed down the adder / processing element chain and that it consists of partial sums as data in Figure 3 and 5:65-6:20. Bui is a filter,

Art Unit: 2628

where this kind of filter inherently consists of weight functions that are 'partial sums', where each tap in such a filter very clearly causes a partial sum as the outcome, see for example the weights on the multipliers in Figures 1-4. Bui performs accumulation, as discussed in 1:65-2:10.

As to claim 30, this is an obvious variation and is addressed in the rejection to claim 21 and is repeated herein. Obviously, the system of Inada outputs pixels as set forth in paragraphs [0022-0024]. Clearly, the results of all the graphics calculations and convolutions would be passed out as pixel data as shown there, and it is logical that the end results of an image convolution calculation from a chain would indeed be output as pixels – indeed, an image is fundamentally composed of pixels, and it is a fundamental of the digital signal processing art that an image is output in pixels from being processed in this context. Motivation and combination are incorporated by reference from the parent claim.

As to claim 32, Inada clearly addresses this limitation wherein it would be obvious to divide the screen up into bins and assign each one to an FPGA or processing element or filtering element, whatever the generic terminology for the groups of Wilson or the elements of Bui.

As to claim 33, Clearly the system of Inada establishes in [0154] that the system breaks the screen down into blocks of 4x4 pixels for interleaving, which constitutes a distribution across screen space, and further in Fig. 1 it is shown how the screen is divided into smaller areas, where each area is analyzed for the presence of a primitive in the pixels in that particularly, smaller area. Further,

Art Unit: 2628

Wilson teaches the division of an image into blocks for processing and convolution purposes. That being said, It would have been obvious to one having ordinary skill in the art at the time the invention was made to combine the systems of Wilson and Bui for the reasons set forth above (the motivation and combination of claim 2 are herein incorporated by reference) with the system of Inada, to allow interleaving as that technique speeds up drawing time (Inada [0155]).

As to claim 36, this is a trivially obvious variant of claim 30 is subject to the same rejection.

As to claim 37, this is a trivially obvious variant of claim 33 and is subject to the same rejection.

Claims 4 and 34 are rejected under 35 U.S.C. 103(a) as unpatentable over Wilson, Bui, and Inada as applied to claim 3 above, and further in view of Hsieh et al (US 6,819,321 B1).

As to claim 4, Wilson and Bui do not expressly teach these limitations; Inada clearly teaches dividing the screen into a plurality of bins but does not specifically teach sixteen sample managers and a four by four array of bins. Reference Hsieh et al teaches dividing the screen into a number of bins for two-dimensional image processing, where the number can be arbitrary, but where an example given is four bins in Figure 4 (3:28-40). Applicant has not established any criticality to the number of sample managers and/or bins, and as such the choice of an arbitrary number of 'sample managers' or processing elements and

Art Unit: 2628

the division of the screen into some arbitrary number of bins is a matter of design choice, see *In re Harza*, 274 F.2d 669, 124 USPQ 378 (CCPA 1960). It would have been obvious to one of ordinary skill in the art at the time the invention was made to modify Inada, Wilson, and Bui to use arbitrarily scaled bins as per Hsieh, since Hsieh decreases memory bandwidth required and provides numerous other benefits (see 2:20-40 and Abstract).

As to claim 34, it is identical to claim 4, and the rejection to which is incorporated by reference.

Claims 5, 7, and 37 are rejected under 35 U.S.C. 103(a) as unpatentable in view of Wilson and Bui as applied to claim 1, and further in view of Cloutier.

As to claim 5, Wilson and Bui do not expressly teach this limitation. Cloutier clearly teaches a plurality of groups of FPGAs in Figure 1, with these controllable by the SIMD process controller. Cloutier Fig. 1 clearly illustrates a plurality of FPGAs configured in a matrix connection, all with global bus connections, and Fig. 3 illustrates similar connections between PEs on one FPGA. It is notoriously well known that an FPGA can be configured to emulate any other type of processor, e.g. the system of Wilson/Bui as noted above. Cloutier teaches that such a system works quickly and is more efficient for processing images and the like. Cloutier clearly establishes that as set forth above that each PE performs convolution based on weighted partial sum operations. Furthermore, the nature of convolution is such that once partial sums

Art Unit: 2628

are computed, they must be acted on by other elements or processors to produce the final, desired results.

As such, examiner takes the position that explanations cited above in response to each element of the portion of the claim dealing with the computation and/or calculation of partials sums more than adequately meet all of the limitations set forth by that section of the claim. Further, any PE that received partials sums from the bus would clearly add them using the multiply-accumulate operations cited above, particularly in the case of a neural network that was being used to perform convolution, which would be obvious to do since the system of Cloutier clearly has established utility for performing both tasks, and optical character recognition (OCR), which requires convolution and pre-processing. Further, Cloutier clearly teaches the applicability of his system to image processing in 4:20-35. Cloutier 7:26-55 again, where it is well known that the partial sums must be added, and 4:20-35, where it is taught that the preferred embodiment is well suited for matrix and vector addition and multiplication. More specifically, the embodiment of Cloutier is taught to perform multiply-accumulate operations (8:50-9:15), which clearly requires that the network of processing elements perform multiply-accumulate operations per tile (with each processing element performing said operations), and in a neural network application, which provides feed-forward information (e.g. feedback) for pattern recognition and similar, multiply-accumulate operations used in the processing of an image would obviously be added and passed along, as the architecture of Cloutier as shown in Fig. 1 is such that data is passed along between elements in the additive fashion

Art Unit: 2628

as set forth above. Also, the system performs convolution and uses partial sums, which clearly requires that the accumulated partial sums be passed to other elements. Cloutier clearly establishes in 7:26-55 that the system has many processing element, each of which computes its own partial sums for convolution purposes.

In light of all of the above, it would have been obvious to one of ordinary skill in the art at the time the invention was made to combine the system of Wilson/Bui with that of Cloutier, such that each FPGA emulated the system of Wilson/Bui and therefore allowed each section to handle one portion of screen space, as this parallel computation would inherently be faster since the parts would be duplicated and the net speed would increase. This is notoriously well known in the art.

As to claim 7, this is a duplicate of claim 2, the rejection to which is incorporated by reference.

As to claim 38, this is a duplicate of claim 5, the rejection to which is incorporated by reference in addition to the rejection to claim 37 above.

Claim 6 is rejected under 35 U.S.C. 103(a) as unpatentable over Wilson/Bui in view of Cloutier as applied to claim 5 above, and further in view of Hsieh.

Therefore, the rejection of claims 2 and 5 are incorporated by reference, and motivation and rationale are taken from each of them.

Art Unit: 2628

As to claim 2, clearly all of the processing elements in Fig. 1 and Fig. 3 of Cloutier are clearly connected via the global bus anyway, which clearly meets the requirements that all the sample manager be chained, and that the final member calculates pixel values – clearly each chip is computing pixel values from the results of the prior one – see Cloutier 7:7-67. Further, as explained above in the rejection to claim 1, the FPGAs and the PEs within each FPGA are all interconnected, and the PEs and the FPGAs can clearly be connected in a chain or serial fashion, as the very nature of an FPGA is that the blocks can be set to have any desired set of connections with bidirectional or unidirectional communications.

Reference Hsieh et al teaches dividing the screen into a number of bins for two-dimensional image processing, where the number can be arbitrary, but where an example given is four bins in Figure 4 (3:28-40). Applicant has not established any criticality to the number of sample managers and/or bins, and as such the choice of an arbitrary number of 'sample managers' or processing elements and the division of the screen into some arbitrary number of bins is a matter of design choice, see *In re Harza*, 274 F.2d 669, 124 USPQ 378 (CCPA 1960). It would have been obvious to one of ordinary skill in the art at the time the invention was made to modify Inada, Wilson, and Bui to use arbitrarily scaled bins as per Hsieh, since Hsieh decreases memory bandwidth required and provides numerous other benefits (see 2:20-40 and Abstract).

References Wilson and Bui do not expressly teach this limitation, whilst Reference Cloutier teaches in 7:28-40 specifically that a matrix of 8x4 PEs is

Art Unit: 2628

implemented on each FPGAs where there is a 2x2 array of FPGAs in the first place, and Inada provides additional support. Given this, it would be reasonable to use a 4x4 array instead of an 8x4 array, given that each FPGA could easily be partitioned into a 4x4 array, as illustrated in Figure 3 anyway. Now, as set forth in the rejections to claims 1-3 above, the system of Cloutier is taught for use with image convolution, and further in Inada the use of interlaced scans is taught, such that the screen is divided up into units of say 4x4 pixels for faster drawing time. Therefore, if one FPGAs with a 4x4 array of PEs, or a 2x2 array of FPGAs with a 2x2 PE implementation, with each one dedicated processing a certain portion of the screen was used, and interleaving was used for the results, it would logical to use the claimed 4x4 architecture. Motivation and combination is taken from the parent claim and herein incorporated by reference, with additional motivation as set forth in the immediately preceding paragraph.

Claim 22 is rejected under 35 U.S.C. 103(a) as unpatentable over Wilson, Bui, and Inada as applied to claim 21 above, and further in view of Hsieh et al (US 6,819,321 B1).

As to claim 22, references Wilson and Bui do not teach this limitation; Inada clearly teaches dividing the screen into a plurality of bins but does not specifically teach sixteen sample managers and a four by four array of bins. Reference Hsieh et al teaches dividing the screen into a number of bins for two-dimensional image processing, where the number can be arbitrary, but where an example given is four bins in Figure 4 (3:28-40). Applicant has not established

Art Unit: 2628

any criticality to the number of sample managers and/or bins, and as such the choice of an arbitrary number of 'sample managers' or processing elements and the division of the screen into some arbitrary number of bins is a matter of design choice, see *In re Harza*, 274 F.2d 669, 124 USPQ 378 (CCPA 1960). It would have been obvious to one of ordinary skill in the art at the time the invention was made to modify Inada, Wilson, and Bui to use arbitrarily scaled bins as per Hsieh, since Hsieh decreases memory bandwidth required and provides numerous other benefits (see 2:20-40 and Abstract).

Claims 23 is rejected under 35 U.S.C. 103(a) as unpatentable over Wilson, Bui, Inada, and Cloutier.

As to claim 23, this is a duplicate of claim 21, which is incorporated by reference, with the additional limitations from claim 5 above, the rejection to which is also incorporated by reference. Wilson uses groups of eight processors that can be configured into different exemplary configurations anyway, and Cloutier is dynamically reconfigurable as pointed out above. Also, Inada is **only** included for division of screen space, which examiner contends would be a notoriously and trivially obvious variant anyway.

Claim 24 is rejected under 35 U.S.C. 103(a) as unpatentable over Wilson, Bui, Cloutier, and Inada as applied to claim 3 above, and further in view of Hsieh et al (US 6,819,321 B1).

Art Unit: 2628

As to claim 24, Inada clearly teaches dividing the screen into a plurality of bins but does not specifically teach sixteen sample managers and a four by four array of bins. Reference Hsieh et al teaches dividing the screen into a number of bins for two-dimensional image processing, where the number can be arbitrary, but where an example given is four bins in Figure 4 (3:28-40). Applicant has not established any criticality to the number of sample managers and/or bins, and as such the choice of an arbitrary number of 'sample managers' or processing elements and the division of the screen into some arbitrary number of bins is a matter of design choice, see *In re Harza*, 274 F.2d 669, 124 USPQ 378 (CCPA 1960). It would have been obvious to one of ordinary skill in the art at the time the invention was made to modify Inada, Wilson, Bui, and Cloutier to use arbitrarily scaled bins as per Hsieh, since Hsieh decreases memory bandwidth required and provides numerous other benefits (see 2:20-40 and Abstract).

Conclusion

The prior art made of record and not relied upon is considered pertinent to applicant's disclosure.

US 6,504,959 to Lee, which discusses cascaded filter elements, which applicant should closely examine.

US 4,984,286 to Dolazza, which is a convolution filter.

Any inquiry concerning this communication or earlier communications from the examiner should be directed to Eric Woods whose telephone number is 571-272-7775. The examiner can normally be reached on M-F 7:30-5:00.
